

Asymbiotic seed germination and seedling development of *Vanda dearei*

Abstract

The effects of basal media, complex additives, plant growth regulators and carbon sources on in vitro seed germination and seedling development of *Vanda dearei* are reported. Immature seeds from four months old capsule were used as plant materials. All cultures were grown under 24h light at $25\pm 2^{\circ}\text{C}$. Results showed that seeds cultured on Knudson C (KC) basal medium germinated after 25 days with $63.0\pm 3.2\%$ germination rate followed by half-strength Murashige & Skoog ($\frac{1}{2}\text{MS}$) ($45.4\pm 10.4\%$) and Vacin and Went (VW) ($41.8\pm 4.0\%$). Addition of 0.5% (w/v) yeast extract significantly enhanced ($85.9\pm 0.7\%$) seed germination and shortened germination time to 23 days. A NAA at 0.1mg/l had similar performance ($80.2\pm 20.5\%$), however, this treatment delayed seed germination and induced necrosis to protocorm development. Sucrose at 1% (w/v) also enhanced seed germination ($98.3\pm 2.3\%$), while glucose and fructose treatments showed moderate effects. For growth and development of protocorms, KC basal media recorded the highest percentage of protocorm with root ($37.0\pm 4.3\%$), mean number of leaf (4.50 ± 1.00) and mean number of roots produced (2.0 ± 0.6) with largest leaf area ($3.7\times 2.3\text{mm}$) and longest root length ($11.7\pm 8.4\text{mm}$). Addition of 20% (v/v) coconut water significantly improved protocorm development and shoot growth.
